Partial Evaluation of Computation Process—an Approach to a Compiler-Compiler

Yoshinoko Futamata, Member
Central Research Laboratory, Hitachi, Ltd., Kōanbunji, Tokyo, Japan 185

SUMMARY

This paper reports the relationship between formal description of semantics (i.e., interpreter) of a programming language and an actual compiler. The paper also describes a method to automatically generate an actual compiler from a formal description which is, in some sense, the partial evaluation of a computation process.

The compiler-compiler inspired by this method differs from conventional ones in that the compiler-compiler based on our method can describe an evaluation procedure (interpreter) in defining the semantics of a programming language, while the conventional one describes a translation process.

1. Introduction

It is known that there are two methods to formally describe the semantics (meaning) of programming languages. One of them is to describe the procedure by which the language to be defined is translated into another language whose semantics are already known; i.e., a description of a translator. The other is to describe a procedure evaluating the results of a statement belonging to the language to be defined (source program); i.e., a description of an interpreter.

In a conventional compiler-compiler, the description of a translator is used to describe the semantics of a programming language. That is, the users of a conventional compiler-compiler have to write the translation program in terms of a translator description language in defining the semantics of a programming language.

The difficulty in writing a translator has been pointed out by Feldman [1] as follows:

"One of the most difficult concepts in translator writing is the distinction between actions done at translate time and those done at run time. Anyone who has mastered this distinction has taken the basic step towards gaining an understanding of computer language."

In describing the semantics of a programming language by an interpreter it is not necessary to set up a distinction between those actions. Therefore, describing an interpreter seems easier than describing a translator. Actually, description by an interpreter is implicitly used at many places in the report: on ALGOL 60 (2) and in manuals of many programming languages. The interpreters of such complex languages as ALGOL 60 and PL/I also have been described formally [3, 4].

However, for reasons described in Sect. 3, a so-called interpreter is often not as efficient as a so-called compiler in language processing.
This paper describes an algorithm to automatically transform an interpreter to a compiler and its application in a compiler-compiler. The algorithm is a sort of partial evaluation procedure (see Fig. 1).

Partial evaluation of a computation process is by no means a new concept [1]. Even in programming languages, POP-2 [6] implies a somewhat similar concept called "partial application." Nevertheless, it is the author’s belief that this paper is the first instance in which the concept is applied in a compiler-compiler. What kind of partial evaluation algorithm is applicable to a compiler-compiler? Is it the purpose of this paper to prove the properties of that algorithm.

2. Partial Evaluation

The following transformation is called a partial evaluation of a computation process \( \pi \) with respect to variables \( c_1, \ldots, c_m \) at the values \( d_1, \ldots, d_m \). In a computation process \( \pi \) containing \( m+\) variables \( c_1, \ldots, c_m, r_1, \ldots, r_n \), evaluate the portions of \( \pi \) which can be evaluated using only the values \( c_1, \ldots, c_m \) assigned to variables \( c_1, \ldots, c_m \), respectively, and constants contained in \( \pi \). The portions which cannot be evaluated unless the values of the remaining variables are given are left intact. Thus, \( \pi \) is transformed into a computation process having \( n \) variables. When the computation process thus obtained is evaluated for values \( r_1, \ldots, r_n \) assigned to variables \( r_1, \ldots, r_n \), respectively, its result is equivalent to the result of evaluation of \( \pi \) for the values \( c_1, \ldots, c_m, r_1, \ldots, r_n \) given to variables \( c_1, \ldots, c_m, r_1, \ldots, r_n \), respectively. We denote this transformation by the equation

\[
\pi(c_1, \ldots, c_m, \ldots, r_n) = \pi(c_1, \ldots, c_m, \ldots, d_1, \ldots, d_n) \quad (1)
\]

We call \( \pi \) the "partial evaluation algorithm." \( c_1, \ldots, c_m \) the "partial evaluation variables," and \( r_1, \ldots, r_n \) the "remaining variables," respectively. We may refer to the usual evaluation as a total evaluation as opposed to a partial evaluation.

Example. Consider the evaluation of a computation process given by the function \( f(x, y) = g(x + y, x - y) \) with the values \( x = 2, y = 3, 4, \ldots, 10 \).

When we evaluate \( f(3, 4) \) for each value of \( y \), i.e., when we execute

\[
x = 3; \quad y = i + 1; \quad z = f(x, y)
\]

3) multiplications and 4) additions are performed. Representing the times elapsed in addition and multiplication by \( a \) and \( m \) respectively, the above computation requires about \( 25(a + 3m) \).

If we have \( \pi(f(x, y) = g(x + y, x - y)) \) by partial evaluation of \( f(x, y) \) with respect to \( x = 1 \), the elapsed time of the partial evaluation, \( a \) + \( m \), is more than \( 2a + m \), i.e., \( k > 2a + m \) (because the partial evaluation involves the evaluation of \( g(x, x) \)).

If we execute

\[
\lim_{y \to \infty} \frac{a + m}{n} \quad \text{and} \quad \frac{a + m}{n} = \frac{k}{n} + 1
\]

a computation time of about \( (2a + 2m)k \) is required. Therefore, when the relation

\[
1 + \frac{a + m}{n} < 
\]

holds, the partial evaluation gives a faster computation.

3. Generation of a Compiler from an Interpreter

An interpreter of a programming language is a computation process containing variables. A sentence (source program) of the programming language is substituted for one of the variables as a value. Variables contained in an interpreter, e.g., \( \text{int} \), are classified into two groups as follows. All variables to which a source program and information needed for syntax analysis and semantic analysis are given as values are classified as a group \( s \). The other variables are classified as a group \( r \). Here, \( \text{int} \) is assumed to have two variables \( s \) and \( r \). The result of the partial evaluation of the interpreter with respect to \( s \) at a given value \( s' \) is \( s(\text{int}, s') \). With \( r' \) assigned to \( r \) as a value, the following relation is derived from Eq. (1):

\[
\text{int}(s', r') = \text{int}(s(\text{int}, s'), r') \quad (2)
\]

If all the computations concerning \( s' \) have been performed at partial evaluation time, the generated computation process \( \text{int}(\text{int}, s') \) does not contain the computation process for syntax and semantic analysis of the source program \( s' \). Moreover, it brings about the same result as \( \text{int}(s', r') \) when it is evaluated for the data \( r' \). Therefore, \( \text{int}(\text{int}, s') \) can be viewed as a computation process which is translated from \( s' \) into the semantic metalanguage describing the interpreter. Namely, it can be regarded as an object program corresponding to \( s' \).

If \( x \) is partially evaluated with respect to \( \text{int} \) on the right side of Eq. (2), the following relation is derived:

\[
\text{int}(s, r') \Rightarrow a(\text{int}, s'), \text{int}(s', r') \quad (3)
\]

Thus, \( \text{int}(s, s') \) can be considered to be a compiler because it generates an object program from \( s' \) operating on it.
Suppose \(\alpha\) has the following two properties.

\(\alpha\) is the computation time of the process. \(\pi\) is the time it takes to evaluate the given value of the computation variables. Property \(\alpha\) reduces the computation time of a partial evaluation.

If a partial evaluation algorithm somehow possesses both properties \(\alpha\) and \(\rho\), it is more efficient to execute a source program once compiled than to interpret it directly when the source program contains such iterations as loops and recursive calls or is iteratively executed for many input data.

The simplest partial evaluation algorithm is the one which only substitutes property \(\alpha\), i.e., the one which only substitutes given values for partial evaluation variables.

The algorithm \(\alpha_1\) considering the property \(\alpha\) and fitted for the partial evaluation of an interpreter is described in the rest of this section.

For ease of explanation, a computation process is represented by a graph such as that in Fig. 2. In Fig. 3 nodes (o) represent conditional branching points, branches (arrow) represent subcomputation processes not containing a branching point and a flow of control, and the leaves (e) represent the termination points of the computation process. All nodes and branches are numbered (a different one is subscripted by a different number), respectively.

Let \(b\) denote the entry branch (there may be more than one entry branch, but we assume that only one is selected at partial evaluation time) and let \(m\) denote the total number of branches.

\(\alpha_1\) determines partial evaluation variables and the remaining variables at each stage of the partial evaluation according to the following two criteria:

1. Partial evaluation variables of the preceding stage or constants or variables (or formal parameters of functions) to which values depending only on partial evaluation variables of the preceding stage or constants are assigned (or given in actual parameters of functions) are partial evaluation variables.

2. Remaining variables of the preceding stage or variables (or formal parameters of functions) to which values depending on the remaining variables of the preceding stage are assigned (or given in actual parameters of functions) are remaining variables.

The algorithm \(\alpha_1\) is given by the five operations below (in the description of the algorithm, integer variables \(a, j(1), \ldots, j(m)\) and a list variable \(L\) are used).

1. Set each of \(j(1), \ldots, j(m)\) to 1 and set \(L\) to null. Proceed to operation (2).

2. Allocate the first address of a space in which the result of partial evaluation of \(b_1\) is stored and memorize that address. (When the result is stored in the memory of a computer as a program the first address is that of the program; when the result is written as a graph the first address is that of a label attached to an entry point to a branch.) Namely, \(\alpha_1\) enters the triplet \((b_1, b_1[j(1)], a[j(1)]\) in \(L\), where \(b_1[j]\) denotes the set of pairs of partial evaluation variables (at the entry point of the \(j\)th entry to \(b_1\) and its values, and \(a[j]\) denotes the first address of the space in which the product of the \(j\)th partial evaluation of \(b_1\) is generated. Proceed to operation (3).

3. Evaluate the partial evaluation of \(b_1\) which can be evaluated only with partial evaluation variables and constants. To those portions attach marks indicating that they have already been evaluated. Let \(b_1[j]\) denote the new computation process generated by this operation \((b_1[j]\) is a new computation process generated from \(b_1\) and \(b_1\) is left intact). Increment the value of \(j(j)\) by 1 and proceed to operation (4).

4. If the process next to \(b_1\) (i.e., the arrow head of \(b_1\)) is a termination symbol (e), stop the partial evaluation. If the process next to \(b_1\) is a conditional branching point \(a[j]\), proceed to (4.1) or (4.2).

4.1 If \(a[j]\) can be evaluated only with the values of partial evaluation variables and
constants, then select one of the two branches based upon the value of \( n_{ij} \). Let \( b_{ij} \) express the branch selected. Set the value of \( g \) to \( p \) and proceed to operation (5).

(4.2) If \( n_{ij} \) cannot be evaluated unless the values of remaining variables are given, then \( n_{ij} \) is left intact. Let \( b_1 \) and \( b_2 \) denote two branches following \( n_{ij} \). Set the value of \( g \) to \( p \) and proceed to operation (5). Next, set the value of \( g \) to 0 and proceed to operation (5).

(5) Examine fig. 5 to see whether there is a triplet whose first and second terms coincide with \( b_1 \) and \( S_{ijlj} \) respectively.

(5.1) If there is such a triplet transfer control of the generated computation process to the position indicated by the third term \( S_{ijlj} \) of the triplet (if a generated computation process is written on paper, draw an arrow to the place labeled \( S_{ijlj} \)). Stop the partial evaluation.

(5.2) If there is no such triplet, return to operation (2).

Example 1. Suppose that the conditional branching points \( a_1, a_2 \) and \( a_3 \) can be evaluated only with partial evaluation variables and constants, and that each evaluation of \( a_1, a_2 \) and \( a_3 \) selects the branch \( b_1, b_2 \) and \( b_3 \) respectively. Then, \( a \) is transformed by \( a_1 \) as described in Fig. 5.

Example 2. Consider the case in which \( a_1 \) and \( a_3 \) can be evaluated only with partial evaluation variables and constants, and the value of \( a_2 \) depends on the values of remaining variables. Let \( a_1 \) always select branch \( b_1 \) and let \( a_3 \) select branch \( b_3 \) the first time and select branch \( b_3 \) the second time. Then, \( a \) is transformed by \( a_1 \) as described in Fig. 4.

Example 3. In Example 2, if \( a_3 \) invariably selects \( b_3, a_1 \) does not always terminate its computation and generates such an infinite graph as described in Fig. 5. However, if \( b_3 \) always selects \( b_1 \) simply because the partial evaluation variables of \( b_3 \) are modifiable, the computation of \( b_2 \) is terminated by operation (5) and produces such a result as described in Fig. 6 in the case when the values of partial evaluation variables of \( b_3 \) do not change. Partially evaluating an interpreter with respect to a source program which contains loops or recursive calls, the above case occurs. Therefore, operations (2) and (5) are essentially important for the compiler-compilation method described in this paper.

Example 4. Let us assume that \( a_2 \) in Fig. 7 depends on the remaining variables. In this case, if the iterative partial evaluation of process \( b_1 \) does not produce the same \( a_2 \) more than once, then an infinite graph will be generated. But in totally evaluating the process it is possible that, after \( b_3 \) has been computed several times, \( a_1 \) selects \( b_3 \) and the computation will terminate. If \( b_3 \) does not contain remaining variables but contains an infinite loop and if \( a_1 \) always selects \( b_3 \) in total evaluation, then it is a trivial example of a computation process whose total evaluation terminates but whose partial evaluation does not terminate.

The evaluation of these portions of a computation process which are not evaluated at total evaluation time, as in the last example, can be avoided by the following procedure. The portions of a computation process (with the exception of conditional branching points) for which it is not known whether they are evaluated at total evaluation time (i.e., no portions following conditional branching points whose values depend on the values of remaining variables) are not
evaluated at partial evaluation time, but the values
are only substituted for the remaining vari-
ables. This procedure is necessary not only
for the avoidance of wasteful evaluations at par-
tial evaluation time but also to guard against the
principles of erroneous statements and other
troublesome portions of the interpreter which do
not have to be evaluated at partial evaluation
time (e.g., input–output operations).

We make an exception of conditional branching
points in the foregoing procedure in order to
reduce the number of nodes and branches con-
tained in the resulting computation process of a
partial evaluation by evaluating as many condi-
tional branching points at partial evaluation
time as possible. If the portions of a computation
process that follow conditional branching points
containing remaining variables contain remain-
ing variables, \( \varphi_1 \) is recursively applied to those
portions. This is based on the idea that because
the portions of a computation process containing
remaining variables often include recursive
calls for an interpreter, it is worthwhile to risk
the partial evaluation of those portions. There-
fore, functions, procedures and pseudo–varia-
bles which do not have to be evaluated at partial
evaluation time must be marked and must be
handled exceptionally.

However, if we describe an interpreter care-
fully, we can avoid such a meaningless loop as
the one described in Example 4. Therefore, the
desired algorithm can be obtained by modi-
fying \( \varphi_1 \) so that it evaluates all the portions of
a computation process except those marked as
unnecessary to be evaluated at partial evaluation
time.

The partial evaluation algorithm has been
described in the preceding discussion, but the
details thereof have been omitted since they are
quite different in each programming language
descibing a computation process.

Example 5. Partial evaluation of the Lisp [7]
function append [\( m \)] defined as

\[
\text{append}(x, y) = \text{null} \iff y = \text{null} \iff x = \text{null} \iff \text{append}((x, y))
\]

Therefore,

\[
a_1, \text{append}((A, B)) = \text{cons}([A; \text{null}]) \iff (B; \text{null}) = \text{null} \iff A = \text{null} \iff \text{append}((A, B))
\]

T – append[A; x] = \text{append}((A, B); \text{null}[(x)])

Example 6. Partial evaluation of ALGOL
program.

Let \( a \) and \( b \) denote lists of integers (i.e.,
integer arrays). \( |a| \) and \( |b| \) contain the length
of each list respectively. \( a[1], a[2], \ldots, a[|a|] \)
and \( b[1], b[2], \ldots, b[|b|] \) contain the elements
of the lists. The program [8] concatenating lists
\( a \) and \( b \) is described below (where \( \text{higm} \) denotes
the upper bound of array \( a \)).

\[
\text{higm} = \begin{cases} 
\forall i \in [0, |a| + |b|], & \text{higm} \text{ instance ovew} \\
& \text{for } i = 0 \text{ to } |a| \\
& \text{for } i = |a| + 1 \text{ to } |a| + |b| \\
& \text{for } i = |a| + |b| + 1 \text{ to } |a| + |b| + \text{higm} \\
\end{cases}
\]

\[
\text{higm} = \begin{cases} 
\forall i \in [0, |\text{higm}|], & \text{higm} \text{ instance ovew} \\
& \forall i = 0 \text{ to } |b| - 1 \\
& \forall i = |b| \text{ to } |b| + |a| - 1 \\
& \forall i = |b| + |a| \text{ to } |b| + \text{higm} - 1 \\
\end{cases}
\]

4. Discussion

(a) What is the criterion for the possibility of
generating a compiler from an interpreter, i.e., a
sentential sufficient condition of termi-
nation of partial evaluation?

(b) Which parts of the object program (i.e.,
the result of partial evaluation of an interpreter
with respect to a source program) are more
efficient than the corresponding parts of the
source program and to what extent? What are
the characteristics of the object program and
how may it be optimized (with respect to time
and memory)?

(c) Quantitatively, to what extent is describ-
ing an interpreter easier than describing a trans-
lator? Can we find a partial evaluation algorithm
generating a compiler which is as efficient as
a compiler generated from a translator?

(d) What kind of semantic metalanguage shall
we use to describe an interpreter in order to
achieve sufficient partial evaluation of the inter-
preter?

At present the author cannot answer the above
questions clearly. It is considered that investiga-
tions along the following lines will solve these
questions.

(1) Understanding structures of interpreters
of programming languages,

(2) Development of a semantic metalanguage
which can be efficiently compiled and by which
we can easily describe the abstract syntax of
programming languages, the state of interpret-
ating machines (stack, table, list, etc.) and their
transitions, numerical computation, and list
processing.

(3) Implementation of a complete partial
evaluation algorithm for a specific semantic
metalanguage.

(4) Theoretical study on the partial evalua-
tion of computer programs.

(5) Optimization of semantic metalanguages,
The author has made a little progress on item (3). A partial evaluation algorithm which is almost equivalent to ALGOL has been described in LISP, and a compiler of program features [6] has been generated from the interpreter of program features by the algorithm. The compiler translated ALGOL-like programs written in the program features into an equivalent system of equations. For example,

\[ \text{prog} ([x]; x) = \text{null} ([x]) \]

is translated into

\[ \text{g}([x]) = \text{null}([x]) \]

\[ \text{g}([x]) = \text{null}([\text{null}([x]); x]) \]

where \( g \) is the function names generated by the compiler and \( g([a]) \) is the object program. Superfluous equations such as \( g([a]) = g([a]) \), \( g([a]) = g([a]) \), etc., can be avoided by optimization of the semantic metalanguage (in this case, LISP).

5. Conclusion

The compiler generation method described in this paper is still in the conceptual stage. It remains to determine whether or not the method can be put to practical use in the near future. However, the author hopes that this paper explains the relationship between formal methods of programming language description and actual compilers. It is also hoped that this paper makes a contribution to the study of the compiler.
